

BOSONIC CHERN–SIMONS FIELD THEORY OF ANYON SUPERCONDUCTIVITY

Nathan Weiss

We study the Quantum Field Theory of nonrelativistic bosons coupled to a Chern–Simons gauge field at nonzero particle density. This field theory is relevant to the study of anyon superconductors in which the anyons are described as **bosons** with a statistical interaction. We show that it is possible to find a mean field solution to the equations of motion for this system which has some of the features of bose condensation. The mean field solution consists of a lattice of vortices each carrying a single quantum of statistical magnetic flux. We speculate on the effects of the quantum corrections to this mean field solution. We argue that the mean field solution is only stable under quantum corrections if the Chern–Simons coefficient $N = 2\pi\theta/g^2$ is an integer. Consequences for anyon superconductivity are presented. A simple explanation for the Meissner effect in this system is discussed.

It is now well established that a gas of charged anyons in two spatial dimensions at $T = 0$ is a superconductor. The most compelling evidence for this is from the calculation of the current–current correlator in the Chern–Simons description of the anyon gas. This calculation, which was first done by Kalmeyer and Laughlin [1] in the RPA approximation and since worked on by many authors [2–4], finds a massless pole in the current–current correlator when the anyons are electrically neutral. This implies that a neutral gas of anyons is a superfluid and, as a consequence, a charged gas of anyons exhibits a Meissner effect and is a superconductor.

In the field theoretic work described above one treats the anyons as fermions coupled to a Chern–Simons (statistical) gauge field. It is this coupling which gives the fermions anyonic statistics. It is well known that anyons can be described either as bosons or as fermions [5] coupled to a Chern–Simons field. The coupling, in each case can be adjusted to give the desired statistics. Although most of the field–theoretic work treats the anyons originally as fermions there are many interesting approaches to anyon superconductivity which begins with anyons as bosons [6,7]. Unfortunately it has not been possible to find an appropriate field–theoretic analysis to treat a gas of anyons using the scalar Chern–Simons description.

The main problem blocking such a description is that a noninteracting system of bosons at nonzero density undergoes bose condensation (at $T = 0$ in 2+1 dimensions). This makes a mean field (and consequently an RPA) description of the system coupled to a Chern–Simons field very difficult. It is the goal of this paper to study this question in detail and to derive the consequences of a mean field analysis for anyons which are described as scalars coupled to a Chern–Simons field at nonzero density. We shall see that no homogeneous mean field solution exists and that in mean field theory the system is unstable to the formation of a kind of lattice of vortices [8,9]. We shall present several arguments which suggests that this system of vortices should be a superconductor. This approach differs from that of Refs. [6,7] in that we seek a mean field solution to the scalar field theory which can potentially be improved by RPA or other methods.

We thus consider a gas of nonrelativistic anyons with mass m which can be described by a complex bosonic field ψ coupled to a Chern–Simons “statistical” gauge field A_μ . We introduce a chemical potential μ and assume a Lagrangian of the form

$$i\psi^\dagger (\partial_0 - igA_0) \psi - \frac{1}{2m} |(\nabla - ig\vec{A}) \psi|^2 - \frac{\theta}{2} \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu A^\lambda - \frac{\lambda}{2} (\psi^\dagger \psi)^2 + \mu \psi^\dagger \psi \quad (1)$$

Notice that besides the interaction introduced by the Chern–Simons field we have introduced an additional point–like interaction $\frac{\lambda}{2} (\psi^\dagger \psi)^2$. The reason for this is that in the absence of the Chern–Simons coupling, the above system is known to bose condense. The expectation value of ψ is $\langle \psi \rangle^2 = \mu/\lambda$. Thus, as is well known, the system is unstable (unless $\mu = 0$ in which case any density is possible). The quartic term is thus a mechanism for allowing us to use the chemical potential as a measure of the density. We shall see however that in the presense of the Chern–Simons interaction this will not be necessary as the Chern–Simons interaction itself stablizes the system at nonzero μ . (This is even the case if the quartic interaction is attractive as has been pointed out by Jackiw et. al. [8]).

We begin by trying to find a mean field solution to the equations of motion derived from Eq. (1)

$$i(\partial_0 - igA_0) \psi = -\frac{1}{2m} (\nabla - ig\vec{A})^2 \psi - \mu \psi + \lambda (\psi^\dagger \psi) \psi \quad (2)$$

$$g\psi^\dagger\psi = \theta B \equiv \theta \nabla \times A \quad (3)$$

$$\frac{ig}{2m} (\psi^\dagger D_i \psi - (D_i \psi)^\dagger \psi) = \theta \epsilon_{ij} E_j \quad (4)$$

where E and B are the statistical electric and magnetic fields derived from A and $D_j = \partial_j - igA_j$ is the covariant derivative.

First note that the only covariantly constant solution to the above equations (i.e. a solution for which $D_\mu \psi = 0$) is $\psi = 0$. This is so despite the fact that the chemical potential term drives ψ away from $\psi = 0$. To see this we decompose ψ into its amplitude ρ and its phase Ω

$$\psi = \rho e^{i\Omega} \quad (5)$$

$D_\mu \psi = 0$ now implies that $\partial_\mu \rho = 0$ and that $gA_\mu = \partial_\mu \Omega$. It follows that $B = \nabla \times A = 0$. But Eq. (3) now forces $\rho^2 = 0$. It thus follows that $\psi = 0$. The physical reason for the lack of a covariantly constant nonzero solution is that there is an analog of the Meissner effect at work. A nonzero ψ which is favored by the chemical potential term forces (due to the Chern–Simons interaction) a nonzero magnetic field which is expelled in the presence of a constant nonzero ψ field.

In addition to the lack of solutions with $D_\mu \psi = 0$ there are no covariantly static solutions with $D_0 \psi = 0$. $D_0 \psi = 0$ now implies that $\partial_0 \rho = 0$ and that $gA_0 = \partial_0 \Omega$. Using this, and the fact that $E_i = \partial_0 A_i - \partial_i A_0$ we find from Eq.(4) that

$$E_i = \partial_0 (A_i - \partial_i \Omega) \propto \epsilon_{ij} (A_i - \partial_i \Omega) \rho^2 \quad (6)$$

Since ρ is time independent it follows that $A - \nabla \Omega$ oscillates in time from which it follows that $B = \nabla \times A$ depends on time and thus from Eq.(3) ρ depends on time. This is a contradiction unless $\psi = 0$.

Despite the fact that no covariantly constant solution exists, it is possible to find a solution for which $\partial_0 \psi = 0$ with $A_0 \neq 0$. As is shown in Ref. [8] this can be done by minimizing the energy functional

$$H = \int d^2x \left[\frac{1}{2m} |D_i \psi|^2 - \mu |\psi|^2 + \frac{\lambda}{2} |\psi|^4 \right] \quad (7)$$

subject to the constraint (Eq.(3)) that

$$\nabla \times A = \frac{g}{\theta} |\psi|^2 \quad (8)$$

The term proportional to A_0 in Eq.(2) appears when A_i in Eq.(7) is varied with respect to ψ using the constraint (8). This occurs **provided** A_0 is given by the solution to Eq.(4) with $\partial_0 A_i = 0$. It is now clear that a spatially constant nonzero ψ (as opposed to a *covariantly* constant ψ discussed above) will yield a configuration with infinite energy since the gauge potential for a constant magnetic field necessarily diverges at spatial infinity.

There are now two possibilities. Either $\psi = 0$ is the mean field solution of lowest energy or there exists a lower energy non homogeneous mean field solution. We shall see that at least

for $\lambda \geq 0$ the latter option holds. In fact we shall explicitly construct field configurations with energy $H < 0$.

In general it is not possible to actually find the minimum of the energy for this highly nonlinear system. One approach is to tune λ so that there exist solutions of the Bogomolny [10] type to this system. This requires $\lambda < 0$ i.e. a repulsive interaction. Solutions of this type have been studied in detail by Jackiw et. al. [8] and by Olesen [9] in the absence of the chemical potential term. They do find exact solutions whose structure is that of a lattice of vortices. In this letter we discuss the more general case when an exact Bogomolny solution is not available. The system will be studied using variational methods.

Our first example of a configuration with lower energy than that of the $\psi = 0$ solution consists of a single “vortex” with a total flux Φ . Consider, as a variational ansatz, a configuration for which the radial component of the gauge potential $A_r = 0$ and whose azimuthal component

$$A_\phi = \frac{\Phi}{2\pi g} \frac{h(r)}{r} \quad (9)$$

so that

$$B = \frac{g}{\theta} \rho^2 = \frac{\Phi}{2\pi g r} \frac{dh(r)}{dr} \quad (10)$$

Since $\rho^2 > 0$ it follows that B is always positive and that $h(r)$ is a monotonically increasing function of r . We further demand that $h(r)$ vanish as $r \rightarrow 0$ so that there is no additional delta function source of magnetic flux at the origin. Since the total flux is simply $g \int B d^2r = \Phi \times h(\infty)$ we choose $h(\infty) = 1$.

As a simple example choose

$$h(r) = 1 - e^{-(\xi r)^\beta} \left(1 + (\xi r)^\beta\right) \quad (11)$$

so that $h(r) \sim (\xi r)^{2\beta}/2$ as $r \rightarrow 0$. For a single vortex there is no need to choose Φ to be a multiple of 2π . We shall see later that in the case of a lattice of vortices, this will be essential. In anticipation of this fact we shall consider here a vortex whose flux is 2π . In this case we see that for large r

$$gA_\phi \rightarrow \frac{1}{r} \quad \text{as } r \rightarrow \infty \quad (12)$$

We can eliminate the effects of this $1/r$ tail by letting the phase Ω of the field ψ (Eq.(5)) be given by

$$\Omega = \phi \quad (13)$$

where ϕ is the azimuthal angle. This then implies that $\nabla\Omega = \hat{\phi}/r$ so that $g\vec{A} - \nabla\Omega$ falls off exponentially for large r . This will turn out to be essential for the multi vortex solutions.

Using this ansatz we can now compute the energy of this configuration. For simplicity we consider the case for which $\lambda = 0$. We shall discuss the more general case in a future publication. Using Eq.(7) the energy can be written as

$$H = \int d^2x \left\{ \frac{1}{2m} [(\partial_i \rho)^2 + \rho^2 (gA_i - \partial_i \Omega)^2] - \mu \rho^2 \right\} \quad (14)$$

This integral can be done numerically for arbitrary β and the value of β which minimizes the energy for fixed ξ can be found. This value turns out to be $\beta \sim 1.7$. (One should not take this value of β too seriously since it applies to the single vortex case only and not to the case of a lattice of vortices which is of greater interest.) At this value of β the expression for H is given by

$$H \sim N \left\{ \frac{\xi^2}{2m} \times 1.5 - \mu \right\} \quad (15)$$

where the factor 1.5 is the approximate numerically obtained value. Note that for sufficiently small ξ the energy is lowered below $H = 0$ which is the value of H for $\psi = 0$. We thus see that there exist lower energy solutions than the $\psi = 0$ solution. The energy is lowest when $\xi \rightarrow 0$ which corresponds to a very large (or diffuse) flux tube. In the case of a lattice of vortices we shall see that the tubes do prefer to have a definite finite size.

It is interesting to note that these vortices differ significantly from the usual Abrikosov vortices found in superconductors. First of all the order parameter ρ vanishes outside the vortex. Secondly the magnetic field tends to zero as $r^{2\beta-2}$ at the centre of the vortex. Both of these peculiar properties are a result of the Chern–Simons condition which forces B to be proportional to ρ^2 .

We now move on to multivortex solutions which we shall show lower the energy even more. In fact for a uniform distribution of vortices we shall see that the mean energy density is less than zero. Our technique, as for the single vortex, will be to construct a variational ansatz for a multivortex configuration. We imagine a distribution of n vortices at locations $\vec{r}_1 \cdots \vec{r}_n$. Recall from the single vortex solution that it is imperative that $\psi^\dagger \psi$ vanish at the location of each vortex so that the integral of $(\partial_i \Omega)^2 \rho^2$ converges there. Furthermore no vortex can have a long range $1/r$ component which is uncanceled by a $\partial_i \Omega$ term. If it did, then the integral of $(gA_i - \partial_i \Omega)^2 \rho^2$ over all the other vortices would diverge. The only option is for each vortex to have a flux of $2\pi \times$ an integer so that the $1/r$ piece can be cancelled at infinity. In general vortices with flux 2π (i.e. a single quantum of flux) will provide configurations with the lowest energy (although we shall see cases where this may not be so).

A multivortex ansatz which satisfies all our requirements is

$$g\vec{A}(\vec{r}) = \left(\sum_{i=1}^N \frac{\hat{\phi}_i}{|\vec{r} - \vec{r}_i|} \right) \times \prod_{j=1}^N h(|\vec{r} - \vec{r}_j|) \quad (16)$$

Since $h \rightarrow 1$ for large r we see that this ansatz behaves like a single vortex near each of the vortices. To cancel the long range behavior of $\vec{A}$ we choose the phase Ω of ψ to be

$$\Omega(\vec{r}) = \sum_{i=1}^N \phi(\vec{r}, \vec{r}_i) \quad (17)$$

where $\phi(\vec{r}, \vec{r}_i)$ is the azimuthal angle which the vector $\vec{r} - \vec{r}_i$ makes with some arbitrary axis. As a result the important combination $gA - \nabla \Omega$ goes like

$$g\vec{A} - \nabla\Omega = \left(\sum_{i=1}^N \frac{\hat{\phi}_i}{|\vec{r} - \vec{r}_i|} \right) \left(\prod_{j=1}^N h(|\vec{r} - \vec{r}_j|) - 1 \right) \quad (18)$$

It is now clear that the contribution of this term due to any given vortex ‘C’ at the location of any other vortex ‘D’ vanishes exponentially as the distance between ‘C’ and ‘D’ increases.

We could now proceed by choosing a specific form for $h(r)$ as might be given, for example, by Eq.(11) and minimizing the energy functional from Eq.(14). We can learn much more, however, by doing a general analysis of the form of the answer. Let us, for definiteness, imagine that the vortices are arranged on a square lattice. Let d be the separation between the vortices and let $1/\xi$ be a measure of the size of the vortex (as is given, for example, in Eq.(11)). The energy in Eq.(14) has two pieces. The first piece proportional to $1/m$ and the second proportional to μ .

Using the fact that $g\rho^2 = \theta B$ and the definition of $N = 2\pi\theta/g^2$ and recalling that the total flux per vortex is 2π we can compute the second term in Eq.(14) as

$$\int d^2x \mu\rho^2 = Nn\mu \quad (19)$$

where n is the total number of vortices

$$n = \frac{V}{d^2} \quad (20)$$

where V is the volume of the system. Evaluation of the first term in Eq.(14) is somewhat more involved. The terms proportional to $1/m$ are functions of only ξ and d and have the dimensions $[\text{mass}]^2$. Thus this first term can be written as

$$\frac{1}{2m} Nn\xi^2 \times F(\xi d) \quad (21)$$

where the function F is unknown until the integrals have been done explicitly. But nonetheless it is a function of the dimensionless product of ξ and d [11]. Combining these two terms we can write the total energy

$$H = nN \left(\frac{(\xi d)^2 F(\xi d)}{2md^2} - \mu \right) \quad (22)$$

The behavior of $x^2 F(x)$ for small and large x is easy to determine. If $\xi \rightarrow \infty$ the vortices are very small relative to their spacing and we obtain simply n copies of the single vortex solution. As a result $F \rightarrow \text{constant}$ and thus $x^2 F(x) \rightarrow \infty$ as $x \rightarrow \infty$. On the other hand when $\xi \rightarrow 0$, F diverges very severely since the magnetic field is now nearly constant and the energy thus grows like V^2 . Thus not only F but also $x^2 F(x)$ diverges as $x \rightarrow 0$. As a result, $x^2 F(x)$ reaches some minimum value as x is varied. Let η be this minimum value of $x^2 F(x)$. It is clear that η will be a number of order 1. The precise value depends on the precise form of $h(r)$ and it can be computed. It follows that for this minimum value of ξd

$$H_{\min} = \frac{VN}{d^2} \left\{ \frac{\eta}{2md^2} - \mu \right\} \quad (23)$$

Note that d is still a variational parameter. The minimum value of $H_{\min}$ occurs when $d^2 = \eta/m\mu$ in which case

$$H_{\min} = -V \frac{m\mu^2 N}{2\eta} \quad (24)$$

Note that the condensate provides us with a negative energy density which is thus lower than the energy for the $\psi = 0$ solution.

We conclude that in the context of the variational calculation it is evident that a “condensate” of vortices provides a good candidate for the Mean Field ground state of this system.

But this is not the whole story! Let us now compute the charge Q of one of these vortices in the “lattice”.

$$Q = g \int d^2x \psi^\dagger \psi = Ng \quad (25)$$

There are N anyons in this vortex with a total charge Ng . This is fine if N is an integer. But if N is not an integer then Q is not a multiple of g **and** the number of particles in the vortex is not an integer. Although the mean field solution still exists in this case we should expect to run into serious trouble when we consider quantum fluctuations about this vortex configuration. To see this let us transport one vortex around another vortex. The Bohm–Aharonov phase picked up is now

$$e^{igN \int B d^2x} = e^{2\pi i N} \neq 1 \quad \text{if } N \text{ is not an integer} \quad (26)$$

Thus if N is not an integer these vortices are themselves anyons. If N is rational ($N = p/q$ with p, q integers) then it may be possible to consider a mean field solution with flux $2\pi q$ per vortex. But if N is irrational then it seems clear that the quantum corrections will lead to infinities. It is also likely that quantum corrections will force the number of particles in the vortex to be an integer. They may also ruin the lattice structure of the mean field solution and cause the system to form a liquid.

Let us now concentrate on the case in which N is an integer. We must consider separately the case when N even and when N is odd. In the case N even (which includes the case of semions for which $N = 2$) the vortices are bosons. When one vortex is taken around another, the phase is $\exp(4\pi i)$ which leads to a phase $\exp(2\pi i)$ under interchange. These bosons have a repulsive core. It is well known that bosons with a repulsive core in two space dimensions form a superfluid. (At nonzero temperature there is no long range order in 2+1 dimensions but the superfluidity persists up to some critical (Kosterlitz–Thouless) transition temperature.) If N is odd the vortices are fermions. It is likely that when quantum effects are included the energy will be lowered by combining two vortices into a single vortex with flux 4π . This new mean field vortex will then be a boson which will allow for bose condensation and superfluidity.

It is possible to see from the mean field theory directly how the Meissner effect arises in this theory. To this end let us couple our system to a “real” fixed background electromagnetic field $\mathcal{A}_\mu$. If $\mathcal{A}_0 = 0$ then the mean field problem can be formulated as a search for the minimum of

$$H = \int d^2x \left[\frac{1}{2m} |(\partial_i - igA_i - ie\mathcal{A}_i) \psi|^2 - \mu |\psi|^2 \right] \quad (27)$$

The mean field solution which we found for $e = 0$ will certainly not admit a constant magnetic field $b = \nabla \times \mathcal{A}$. If we choose, for example, a vector potential $\mathcal{A}_2 = bx_1$ with $\mathcal{A}_1 = 0$ then Eq.(27) will have a term $\int d^2x \rho^2(\vec{r}) x_1^2$ which clearly diverges due to the presence of the infinite lattice of vortices.

The above argument is however too crude since it is possible to make new kinds of vortices in the presence of an externally applied magnetic field. One can simply force the **sum** of the flux of the statistical and the real gauge fields to be 2π so that

$$\int d^2x [g\nabla \times A + e\nabla \times \mathcal{A}] = 2\pi \quad (28)$$

while ρ^2 is proportional to only the statistical magnetic field $B = \nabla \times A$. This will yield a perfectly sensible mean field solution for arbitrarily small applied magnetic field. The problem with this solution is that the charge of the vortex will no longer be an integral multiple of g

$$Q = \int d^2x \rho^2 = \frac{gN}{2\pi} \int d^2x \nabla \times A \neq gN \quad (29)$$

and, more importantly, the total number of particles in each vortex will no longer be an integer. As discussed previously the quantum corrections should cause such a configuration to have an infinite energy. As a result, a constant magnetic field is expelled from this system.

Although the bosonic picture of anyonic superconductivity looks on the surface to be dramatically different from the fermionic description there are many similarities. In fact many of the predictions of this model are very similar to those for the fermionic description. For example a crude calculation of the real magnetic field generated by these anyons which should be observable in muon spin rotation experiments agrees quite well with the result obtained in the fermion analysis. Details of this calculation will be given in a future publication. The one major difference between this analysis and the fermionic RPA analysis is in the behavior of the system at nonzero temperature. In the fermionic analysis the RPA calculation alone leads to a loss of superconductivity at nonzero temperature [4]. In the bosonic case we have a conventional Kosterlitz–Thouless kind of superconductor which continues to be a superconductor up to some critical temperature.

In this paper we have discussed a nonrelativistic theory of Bosons coupled to a Chern–Simons gauge field. It is also possible to carry out the analysis of a **relativistic** Chern–Simons model at nonzero density. The details of that analysis differ considerably from the nonrelativistic analysis but the conclusions remain the same. The system forms a lattice of vortices which expected to be a superfluid. Details of the relativistic analysis will also be presented in a future publication.

- [11] The situation is a bit more subtle than is described in the text. There is, in fact also a dependence on the volume V since in the limit where $\xi \rightarrow 0$ the magnetic field becomes nearly constant and the energy grows like V^2 . Fortunately we need not worry about this as long as the minimum of $x^2 F(x)$ occurs for x not too small. This is nearly always the case.
